Mots-clefs : Structured population dynamics, cell cycle, circadian and therapeutic control, entropy methods.

1 Introduction

It is usually believed that each cancer is unique because of the complexity in factors of development such as the variety of tissues, the numerous combinations of genetic alterations, the succession of events as vasculogenesis and angiogenesis ([1], [13]). Several critical events are however common to the evolution of each cancer which are targets for potential therapeutic actions. Among them is the suppression of apoptosis (programmed cellular death) and deregulation of cell proliferation, we refer to [7] for a review of this aspect. This leads to try to understand the tumour development at the level of a population of cells while ‘macroscopic’ models for the neoplastic progression have been widely proposed and validated ([3] and the references therein). One can hope that a better understanding and control of the cell cycle can be used practically in cancer therapy. Our aim is to include in our model two key features of several anti-cancer drugs. The first one is that they act on specific phases of the cell cycle, for instance by promoting or inhibiting transition from a given phase to another, or to apoptosis. The second one is that drugs efficiency and/or toxicity seems to be strongly related to a 24 hours rhythm imposed by our circadian central clock [12].

Several mathematical approaches are proposed to model the cell cycle depending on the expected output one wishes to achieve. Description of a single cell by a system of Ordinary Differential Equations modeling the sequence of biomolecular events has been proposed by several authors and specifically the circadian rhythm is treated in [19]. When a population of cells is considered one is lead to structure the population by ‘age’ in the phase and this is the point of view we use here. The mathematical formalism for this purpose enters the class of Partial Differential Equations. The simplest way to do so is related to the famous McKendrick-Von Foerster model, also called renewal equation (see [2], [14] for instance)

$$\frac{\partial}{\partial t}n(t, a) + \frac{\partial}{\partial a}n(t, a) + d(a)n(t, a) = 0, \quad t \geq 0, a \geq 0, \quad (1)$$

$$n(t, a = 0) = \int_{a \geq 0} b(a)n(t, a) da, \quad (2)$$

$$n(t = 0, a) = n_0(a). \quad (3)$$

Here $n(t, a)$ denotes the density of cells at time t and age a , $d(a)$ the death rate, and $b(a)$ the birth rate. This general model may be specialized to the case

$$b(a) = 2\delta(a = A_b),$$

thus expressing that mitosis (doubling of the cell) arises at given age $a = A_b$. This type of model has been used recently and compared to *in vitro* experiments in [4]. The model we propose below is a generalization of this kind of description. Let us point out that the simplicity of the biological description in such a model led several authors to improvements. For instance different individual cells, under constant environmental conditions, have been proved to exhibit highly variable intermitotic intervals (Lebowitz and Rubinow [11] and the references therein) and this observation led those authors to postulate an improved mathematical model where the population is also structured in terms of a generation time τ , thus leading to the evolution for the cell density $n(t, a, \tau)$

$$\begin{aligned} \frac{\partial}{\partial t}n(t, a, \tau) + \frac{\partial}{\partial a}n(t, a, \tau) + D(a, \tau)n(t, a, \tau) &= 0, \quad t \geq 0, a \geq 0, \tau \geq 0, \\ n(t, a = 0, \tau) &= \int b(a, \tau, \tau')n(t, a, \tau')da d\tau' \\ n(t = 0, a, \tau) &= n_0(a, \tau). \end{aligned} \tag{4}$$

A somewhat related but more general model is that of Rotenberg [17]. Then, the biological hidden variable is a maturation velocity $\mu \in [0, 1]$, and the observable state a is the biological age, more relevant than the physical age, in other words, the degree of maturity (and then a/μ is the physical age in the previous models). Then, the density of population $n(t, a, \mu)$ satisfies the transport equation

$$\frac{\partial}{\partial t}n(t, a, \mu) + \mu \frac{\partial}{\partial a}n(t, a, \mu) + D(a, \mu)n(t, a, \mu) = \int K(a, \mu, \mu')n(t, a, \mu')d\mu', \tag{5}$$

with again boundary conditions at $a = 0$, and initial data at $t = 0$,

$$\begin{aligned} n(t, a = 0, \mu) &= \int b(a', \mu', \mu)n(t, a', \mu')d\mu'da', \\ n(t = 0, a, \mu) &= n_0(a, \mu). \end{aligned}$$

This model enhances the stochasticity in the time evolution of the population thanks to the kernel K which allows a random change of the maturation velocity, and also, as in the previous models, in the birth process. We also refer to [6] for other models with the notion of maturity. In this paper we first present a model which allows to keep more biologically based assumptions than the equation (1)-(2). We refer specifically to the notion of phases in the cycle which allow to introduce controls such as the effect of a circadian clock which blocks periodically the phase transition. We give some mathematical results concerning the solutions and especially the existence of a (Malthus) parameter for the total growth of the population. Then we propose numerical tests to measure the effect of the circadian clock on the total growth.

2 A model for the cell cycle

The cell division (mitosis) is the result of a full cycle that a cell should undergo successfully ([10]). It is usually accepted that the cycle consists in four phases, (i) a growth phase, denoted G1, where mostly the cell doubles its size, (ii) a synthesis phase, denoted by S, where the DNA

is duplicated, (iii) a rest phase, denoted by G2, which is used to check and repair the errors in S phase, (iv) the mitosis, phase M, itself where the two DNA folds separate (anaphase) and the cell divides finally. The important feature for our purpose is that the cell-cycle progression is controlled by proteins (Cyclin Dependent Kinases, CDK in short, see [18]) and thus we wish to keep this notion in the mathematical model. Also much of the cells stay at rest in a quiescent phase called G0, typically, skin cells are constantly in the cycle, endothelial cells are known to stay at rest and may be activated by Vascular Endothelial Growth Factors when angiogenesis occurs. On another hand, the cell cycle duration is also extremely variable, from several minutes to several days, depending on the cells [10], [9].

Our cell population model uses the density of cells in the phase i , denoted by $n_i(t, a)$, at time t and with age a in the cell, and say $i = 0$ for the rest phase G0, and $i = 1, 2, \dots, I$ with $I = 4$ in the above scenario. We call $K_{i \rightarrow i+1}(a) \geq 0$ the transition rate from phase i to phase $i + 1$ depending on the age a in the phase i ($K_{I \rightarrow I+1}$ stands sometimes for $K_{I \rightarrow 1}$ in order to simplify some notations). As a simple model we can have in mind is

$$K_{i \rightarrow i+1}(a) = \psi_i \mathbf{1}_{\{a \geq a_i\}}, \quad \psi_i > 0, \quad (6)$$

a constant rate after some age a_i is attained. These transition rates could be controlled by drugs or by the circadian clock as mentioned in the introduction, thus leading to a variant

$$K_{i \rightarrow i+1}(t, a) = \psi(t) \mathbf{1}_{\{a \geq a_i\}}, \quad (7)$$

then $\psi(t)$ is a switch activated periodically at certain times in the circadian control, by a therapy in case of therapeutic control.

Then the evolution of the density in the phase is modelled via a McKendrick-Von Foerster equation as presented in the introduction. Variable $d_i > 0$ is the death rate in the phase i : as mentioned in our introduction, it could also be controlled by drugs with a circadian rhythm; $v_i(a) > 0$ is the evolution speed in the phase which could also be controlled by some nutriment for instance in phase G1. Hence, for $1 \leq i \leq I$, $t \geq 0$ and $a \geq 0$, we have

$$\begin{cases} \frac{\partial}{\partial t} n_i(t, a) + \frac{\partial}{\partial a} [v_i(a) n_i(t, a)] + d_i(a) n_i(t, a) + K_{i \rightarrow i+1}(a) n_i(t, a) = 0, \\ v_i(0) n_i(t, a = 0) = \int_{a' \geq 0} K_{i-1 \rightarrow i}(a') n_{i-1}(t, a') da'. \end{cases} \quad (8)$$

For $i = 1$, the renewal condition does not make sense because the phase $i - 1$ does not exist and we replace it by

$$v_1(0) n_1(t, a = 0) = 2\tau_M \int_{a' \geq 0} K_{I \rightarrow 1}(a') n_I(t, a') da', \quad (9)$$

where $0 < \tau_M \leq 1$ is the rate of cells which continue the cycle after mitosis. For the sake of simplicity we have not described the phase G0 which receives the extra cells after mitosis and possibly can introduce new cells in the cycle. Of course our model is completed by a Cauchy data set

$$n_i(t = 0, a) = n_i^0(a) \geq 0, \quad \forall i = 1, \dots, I, \quad \forall a > 0. \quad (10)$$

This model thus retains some aspects of Rotenberg [17] model (see the introduction) with a discrete set of maturation states (μ in (5) corresponds to i in (8)) while keeping the main feature that enough phase progression is needed for transition to the next phase. It also has the advantage of indicating clearly possible control points for further modelling. This kind of system can either create exponential growth or exponential decay of the total population size depending on the death and transition parameters and of course the control parameters. This feature is analyzed in next section.

3 Mathematical results

The above system of transport equations is endowed with a natural maximum principle which preserves the nonnegativity of n_i and of a natural L^1 theory which reflects the conservation of densities by the drift term. These are usual properties that can be handled by various well understood mathematical methods and we state an existence result for completeness. More interesting is the large time asymptotic analysis which can hardly be performed here by standard methods based on Laplace transform. We rather use entropy methods introduced in this context in [16], see also [15], [20].

We always assume below that all the (nonnegative) coefficients $(d_i, v_i, K_{i \rightarrow i+1})$ are continuous and

$$\infty > \bar{v} \geq v_i(a) \geq \underline{v} > 0, \quad v_i(\cdot) \text{ is Lipschitz continuous.} \quad (11)$$

$$K_{i \rightarrow i+1}(a) \leq \bar{K} < \infty, \quad (12)$$

$$\frac{d_i(a)}{a} \rightarrow \infty, \quad K_{i \rightarrow i+1}(a) > 0 \quad \text{for } a \text{ large.} \quad (13)$$

Theorem 3.1 (*Existence*) *With the assumptions (11)–(13) and*

$$n_i^0 \in L^1(\mathbb{R}^+),$$

there exists a unique distributional solution $n_i \in C(\mathbb{R}^+; L^1(\mathbb{R}^+))$, $n_i \geq 0$, to the system (8)–(10). It satisfies the a priori bound

$$\sum_{i=1, \dots, I} \int_0^\infty n_i(t, a) da \leq e^{t(2\tau_M - 1) \|K_{I \rightarrow 1}\|_{L^\infty}}. \quad (14)$$

The a priori bound here is very crude and does not use the precise structure of the operators involved in the dynamics. It is aimed to show why L^1 theory is natural through its simplicity. Concerning the time behavior, it turns out that the population grows with an exponential rate of parameter λ . A more accurate result is indeed

Theorem 3.2 (*Long time behavior*) *With the assumptions of Theorem 3.1, there exists a unique parameter $\lambda \in \mathbb{R}$ and unique (up to a multiplicative constant) C^1 functions $\phi_i(a) > 0$, $\phi_i(a) \rightarrow 0$ as $a \rightarrow \infty$ such that*

$$\sum_{i=1, \dots, I} \int_0^\infty n_i(t, a) \phi_i(a) da = e^{\lambda t} \sum_{i=1, \dots, I} \int_0^\infty n_i^0(a) \phi_i(a) da \quad \forall t \geq 0. \quad (15)$$

An explicit formula for the Malthus parameter λ is given below, equation (19), that allows to check whether there is extinction i.e. $\lambda < 0$ or growth i.e. $\lambda > 0$. It can be seen as the first eigenvalue for the underlying operator the existence of which follows by the Krein-Rutman theorem ([5]), but below we give a direct and constructive proof. We can also go further and make more precise the long time asymptotics as follows

Theorem 3.3 (Time asymptotics) *With the assumptions and notations of of Theorem 3.2, there exists a unique positive solution (up to a multiplicative constant) to*

$$\begin{cases} \frac{\partial}{\partial a}[v_i(a)N_i(a)] + [d_i(a) + K_{i \rightarrow i+1}(a) + \lambda]N_i(a) = 0, \\ v_i(0)N_i(a=0) = \int_{a' \geq 0} K_{i-1 \rightarrow i}(a') N_{i-1}(a') da', \end{cases} \quad (16)$$

and one has

$$\int_{a=0}^{\infty} |n_i(t, a)e^{\lambda t} - M_0 N_i(a)| da \rightarrow 0, \quad \text{as } t \rightarrow \infty, \quad (17)$$

with M_0 the constant such that

$$\sum_{i=1, \dots, I} \int_0^{\infty} n_i^0(a) da = M_0 \sum_{i=1, \dots, I} \int_0^{\infty} N_i(a) da.$$

These theorems follows from classical methods which where extended to Rotenberg model in [16]. Notice that the convergence rate in (17) can be proved to be exponential in simple situations, but we do not know of simple formulas based on the coefficients of the equation itself ($d_i, K_{i-1 \rightarrow i}, \dots$). Their proofs are thus simple variants of the arguments that can be found in a more sophisticated form in [16] and we only sketch the main arguments.

Proof of Theorem 3.1. We do not give a proof of this very classical result which is based on Banach-Picard fixed point theorem, and we only mention briefly the derivation of the a priori bound (14). The positivity of the solution is obvious because $(n_i)_-$ (the negative part is defined by $a_- = \max(0, -a)$) is a subsolution with a vanishing initial data and thus remains negative (therefore zero) for all times. The L^1 bound is obtained by integration in age, using the positivity of the d_i

$$\frac{d}{dt} \sum_{i=1, \dots, I} \int_0^{\infty} n_i(t, a) da + \sum_{i=1, \dots, I} \int_0^{\infty} K_{i \rightarrow i+1}(a) n_i(t, a) da \leq \sum_{i=1, \dots, I} v_i(0) n_i(t, 0),$$

therefore, the boundary fluxes exactly compensate (as expected in the model) the transition rates and it remains

$$\begin{aligned} \frac{d}{dt} \sum_{i=1, \dots, I} \int_0^{\infty} n_i(t, a) da &\leq (2\tau_M - 1) \int_0^{\infty} K_{I \rightarrow 1}(a) n_I(t, a) da \\ &\leq (2\tau_M - 1) \|K_{I \rightarrow 1}\|_{L^\infty} \int_0^{\infty} n_I(t, a) da \\ &\leq (2\tau_M - 1) \|K_{I \rightarrow 1}\|_{L^\infty} \sum_{i=1, \dots, I} \int_0^{\infty} n_i(t, a) da, \end{aligned}$$

and the result follows.

Proof of Theorem 3.2. The stationary dual problem to (11)–(12) is given by an eigenvalue problem: find λ such that there is a solution to

$$\begin{cases} v_i(a) \frac{\partial}{\partial a} \phi_i(a) - [d_i(a) + K_{i \rightarrow i+1}(a) + \lambda] \phi_i(a) = -\phi_{i+1}(0) \bar{K}_{i \rightarrow i+1}(a), \\ \phi_i(a) \rightarrow 0 \quad \text{as } a \rightarrow \infty. \end{cases} \quad (18)$$

Here we have used the notation $\bar{K}_{i \rightarrow i+1}(a) = K_{i \rightarrow i+1}(a)$ for $i = 1, \dots, I-1$ and $\bar{K}_{I \rightarrow 1}(a) = 2\tau_M K_{I \rightarrow 1}(a)$

In other words, multiplying (11)–(12) by $\phi_i(a)$, multiplying equation (18) by $n_i(t, a)$ and integrating da and summing up in i , we arrive at

$$\begin{aligned} \frac{d}{dt} \left[e^{-\lambda t} \sum_{i=1, \dots, I} \int_0^\infty \phi(a) n_i(t, a) da \right] - e^{-\lambda t} \sum_{i=1, \dots, I} v_i(a=0) n_i(t, a=0) \phi_i(a=0) \\ = -e^{-\lambda t} \sum_{i=1, \dots, I} \phi_{i+1}(0) \int_0^\infty \bar{K}_{i \rightarrow i+1}(a) n_i(t, a) da, \end{aligned}$$

(this uses the condition at infinity for the dual problem!). After rearranging the sum on the right and taking into account the renewal condition (12), the above equation reduces to

$$\frac{d}{dt} \left[e^{-\lambda t} \sum_{i=1, \dots, I} \int_0^\infty \phi(a) n_i(t, a) da \right] = 0.$$

Therefore the result of Theorem 3.2 is reduced to proving the existence of a solution to the dual problem with the announced properties. To do so, we write the solution when λ is given and show that a single λ is possible in order to satisfy the condition at infinity. We have

$$\phi_i(a) = e^{D_i(a) + \frac{\lambda}{v_i(a)} a} \left[\phi_i(0) - \phi_{i+1}(0) \int_0^a \frac{\bar{K}_{i \rightarrow i+1}(\sigma)}{v_i(a)} e^{-(D_i(\sigma) + \frac{\lambda}{v_i(a)} \sigma)} d\sigma, \right.$$

with

$$D_i(a) = \int_0^a \frac{d_i(\sigma) + K_{i \rightarrow i+1}(\sigma)}{v_i(a)} d\sigma.$$

Because the problem is defined up to a multiplicative constant (we look for the first eigenvalue of a positive operator) we may choose $\phi_1(0) = 1$. Then, the vanishing condition at infinity for ϕ_1 gives

$$\phi_2(0) = \left[\int_0^\infty \frac{\bar{K}_{1 \rightarrow 2}(\sigma)}{v_1(a)} e^{-(D_1(\sigma) + \frac{\lambda}{v_1(a)} \sigma)} d\sigma \right]^{-1}.$$

Notice that our assumptions show that this integral is well defined for $\lambda > \underline{d}/\bar{v}$ at least. The vanishing condition at infinity for ϕ_2 then gives

$$\phi_3(0) = \phi_2(0) \left[\int_0^\infty \frac{\bar{K}_{2 \rightarrow 3}(\sigma)}{v_2(a)} e^{-(D_2(\sigma) + \frac{\lambda}{v_2(a)} \sigma)} d\sigma \right]^{-1}.$$

After a complete cycle, we arrive at the condition

$$1 = \phi_1(0) = \phi_I(0) \left[\int_0^\infty \frac{\bar{K}_{I \rightarrow 1}(\sigma)}{v_I(a)} e^{-(D_I(\sigma) + \frac{\lambda}{v_I(a)} \sigma)} d\sigma \right]^{-1},$$

in other words the value of λ is given by the formula

$$1 = \prod_{i=1}^I \int_0^\infty \frac{\bar{K}_{i \rightarrow i+1}(\sigma)}{v_i(a)} e^{-(D_i(\sigma) + \frac{\lambda}{v_i(a)} \sigma)} d\sigma. \quad (19)$$

A condition that is fulfilled by a single value of λ because this product defines a decreasing and C^1 function, it vanishes for $\lambda \rightarrow \infty$ and it tends to ∞ for $\lambda \rightarrow \underline{d}/\bar{v}$. This concludes the existence of a solution ϕ_i to the dual problem (notice that all the required properties are indeed satisfied) and thus the Theorem 3.2 is proved.

Proof of Theorem 3.3. We refer to [16] for a proof and we just indicate briefly the very reason behind this convergence. First of all, notice that the existence of solutions to equation (16) for N_i follows (by exact formulas) from the same choice as above of the parameter λ (in other words the primal and dual problems have the same first eigenvalue associated to a positive eigenvector!). Next, we have

$$\begin{cases} \frac{\partial}{\partial t}(e^{-\lambda t} n_i(t, a)) + \frac{\partial}{\partial a}[e^{-\lambda t} v_i(a) n_i(t, a)] + [d_i(a) + K_{i \rightarrow i+1}(a) + \lambda] n_i(t, a) = 0, \\ v_i(0) e^{-\lambda t} n_i(t, a = 0) = \int_{a' \geq 0} K_{i-1 \rightarrow i}(a') e^{-\lambda t} n_{i-1}(t, a') da'. \end{cases}$$

Subtracting equation (16) for N_i , and multiplying by $\text{sgn}(e^{-\lambda t} n_i(t, a) - N_i)$ (this is well justified even though the sgn function is not smooth) we arrive at

$$\begin{cases} \frac{\partial}{\partial t} |e^{-\lambda t} n_i(t, a) - N_i(a)| + \frac{\partial}{\partial a} [v_i(a) |e^{-\lambda t} n_i(t, a) - N_i(a)|] + [d_i(a) + K_{i \rightarrow i+1}(a) + \lambda] |n_i(t, a) - N_i(a)| = 0, \\ v_i(0) |e^{-\lambda t} n_i(t, a = 0) - N_i(a = 0)| \leq \left| \int_{a' \geq 0} [K_{i-1 \rightarrow i}(a') e^{-\lambda t} n_{i-1}(t, a') - N_i(a')] da' \right|. \end{cases}$$

Therefore, after integration against the dual solution $\phi_i(a)$, and summation of these equations we arrive at

$$\begin{aligned} & \frac{d}{dt} \sum_{i=1, \dots, I} \int_{a \geq 0} |e^{-\lambda t} n_i(t, a) - N_i(a)| \phi_i(a) da \\ & \leq \sum_{i=1, \dots, I} \phi_i(0) \left[\left| \int_{a \geq 0} K_{i-1 \rightarrow i}(a) [e^{-\lambda t} n_i(t, a) - N_i(a)] da \right| \right. \\ & \quad \left. - \int_{a \geq 0} K_{i-1 \rightarrow i}(a) |e^{-\lambda t} n_i(t, a) - N_i(a)| da \right] \\ & \leq 0. \end{aligned}$$

This proves that the quantity decays but also that the quantity in the right hand side is integrable, that is

$$\int_{t=0}^{\infty} \left| \int_{a \geq 0} K_{i-1 \rightarrow i}(a) [e^{-\lambda t} n_i(t, a) - N_i(a)] da \right| - \int_{a \geq 0} |K_{i-1 \rightarrow i}(a) e^{-\lambda t} n_i(t, a) - N_i(a)| da < \infty,$$

which implies that

$$e^{-\lambda t} n_i(t, a) - N_i(a) \rightarrow 0, \quad \text{as } t \rightarrow \infty,$$

on the support of $K_{i-1 \rightarrow i}(\cdot)$. Then, one can obtain that the full quantity vanishes in using the PDE again and compactness arguments that are detailed in [16].

4 Numerical method: one phase

Before we consider the effect of an outside control on one of the phases, we present the numerical method used here. It is based on an upwind scheme for the transport equation ([8]) in the finite volume spirit. These methods are known to be inaccurate except when an optimal time step can be used: we therefore consider here this optimal situation (CFL=1), this is possible under the restriction that

$$v_i(a) = Cst, \quad \forall i = 1, \dots, I,$$

a condition that we assume from now on with $v_i(a) = 1$, i.e. $\Delta t = \Delta a$ where these are the (uniform) discretization parameters in the two variables t and a . Below we denote by $n_j^n(i)$ the average value of $n_i(t^n, a)$ on the j -th cell in the age variable, at time $t^n = n\Delta t$.

In order to avoid further time restriction, we also consider an implicit scheme for the death rates and transition rates. We arrive at the algorithm:

$$n_1^{n+1}(i) = \Delta t \sum_{j=2, \dots, J} K_{i-1 \rightarrow i}(j) n_j^{n+1}(i-1),$$

$$n_j^{n+1}(i) [1 + \Delta t * (d(j) + K_{i \rightarrow i+1}(j))] = n_{j-1}^n(i), \quad j = 2, \dots, J,$$

(except for $i = 1$ where the cell division factor $2\tau_M$ is added). Here we have in mind that the first point in a represents the flux on the boundary and not an average in a cell. Therefore the point $n_1^n(i)$ is excluded from the discrete renewal kernel.

Figure 1: Solution of the renewal equation (one phase) in case 1 (peaked renewal kernel). Left: the total population density as a function of time. Right: the steady state $N(a)$.

Figure 2: Solution of the renewal equation (one phase) in case 2 (uniform renewal kernel). Left: the total population density as a function of time. Right: the steady state $N(a)$.

For the sake of completeness, we now present results for the case of one phase (McKendrick-Von Foerster equation). They are obtained with $J = 2 * 20$ (20 is the number of discretization points for a unit age time which is the maximal age for renewal in the choice we make below for K i.e. $a_M = 1$ in the two cases below). In other words our simulations are conducted for

$0 \leq a \leq 2 * a_M$ and up to the final time $t_{final} = 3 * a_M$. Also we use a death rate $d(a) = 2 * a / a_M$. It is well known that, after multiplication by the factor $e^{-\lambda t}$, the solution converges to a steady state but with an oscillatory behavior (this is related to the second eigenvalue of the underlying operator which has an imaginary part). This kind of behavior has been confirmed and matched to experiments on cancerous cells in [4]. We also exhibit this phenomenon in the numerical tests below and relate it to the form of the kernel $K(a)$ used for the renewal term. We consider in this case a renewal kernel K with bounded support. We show that the more ‘peaked’ is the kernel K , the more oscillations the solution exhibits. To do so, we consider two cases

- First case. $K(a) = 4 * \mathbf{1}_{\{a_M/2 \leq a \leq a_M\}}$, see Figure 1.
- Second case. $K(a) = 2 * \mathbf{1}_{\{0 \leq a \leq a_M\}}$, see Figure 2.

5 Numerical results on the circadian control

We now come to the case of two phases in the model (8)–(10) for the cell cycle. Still assuming that the cycle speeds are constant, it can be discretized exactly as explained previously in §4 and we do not give additional details.

In this preliminary study, we consider two cases in order to see the effect of an outside (circadian) control that can affect the transitions as motivated in the introduction,

- Third case. No switch is imposed in the transitions between phases, we are in the situation of transition rates given by (6), see Figure 3,
- Fourth case. A switch blocks the transition from phase 1 to phase 2 periodically, as proposed in (7), see Figure 4.

These are merely chosen as a first illustration of possible effects of a circadian control. More systematic and elaborate numerical tests, as well as mathematical and biological interpretations remain to be performed.

The results are shown after normalizing the solution by a growth factor $e^{\lambda t}$, with λ the eigenvalue (Malthus parameter) which has been analyzed in §3. The value λ is of primary importance and is affected by the circadian control: the order of magnitude is $1/3$ for a circadian switch closed one third of the day length and a total cell cycle of approximately one day. The oscillations that appear in Figure 4 have the period of the cell cycle, not the circadian period.

6 Conclusion

Motivated by understanding the role of cell-cycle in tumour developments we have proposed a mathematical model to describe a cell population structured by its age in each phase. This model is especially designed to incorporate control parameters at several, biologically based, points (death rate, transition rates) in order to take into account therapy or circadian clock. A mathematical theory for existence and long time asymptotics has been developed based on entropy methods. The numerical tests are in accordance with this theory and with previous comparisons with experiments in [4]. First numerical results are also given on the effect of a circadian control.

Figure 3: Solution of the cell cycle equation (two phases) in case 3 (no periodic control). Left: the total population density in the first phase as a function of time. Right: the steady state $N_1(a)$.

Figure 4: Solution of the cell cycle equation (two phases) in case 4 (periodic blocking). Left: the total population density in the first phase as a function of time. Right: the steady state $N_1(a)$.

Acknowledgments The authors wish to thank Prof. Francis Lévi and Daniel Claude for fruitful discussions, for indications on the therapeutic control and for pointing out numerous references on the subject.
