Standard models for financial markets are based on the simplifying assumption that trading orders can be given and executed in continuous time with no friction. This assumption is clearly a strong idealization of the reality. In particular, securities should not be described by a single price but by a bid and ask curve. As a first approximation, one may assume that the bid and ask prices do not depend on the traded quantities which leads to models with proportional transaction costs. These models have attracted a lot of attention these lasts years, mostly because their linear structure allows to develop a nice duality theory as in frictionless models.

1 The Theory of No Arbitrage with Proportional Costs

The fictitious markets approach in the one dimensional case

The study of models with proportional transaction costs starts with the seminal paper of Jouini and Kallal [22] who considered a financial market with one non risky asset S^1, taken as a numéraire and normalized to 1, and one risky asset called S^2.

To be consistent with the developments below, we use a different (but equivalent) presentation that the one used in [22]. In particular, we denote by π^{ij} the number of physical units of asset i for which an agent can buy one unit of asset j. With these notations, the bid and ask prices of S^2 in terms of S^1 are given by $1/\pi^{21}$ and π^{12}. They are assumed to be right-continuous and adapted to the underlying (right-continuous) filtration $(\mathcal{F}_t)_{t \leq T}$.

In this model, simple self-financing trading strategies are defined as finite sequences of trading times $(t_n)_{n \leq N}$, for some $N \geq 1$, and random vectors of traded quantities $(\xi_{t_n})_{n \leq N}$ such that ξ_{t_n} is $\mathcal{F}_{t_n}$-measurable. The i-th component $\xi_{t_n}^i$ of ξ_{t_n} stands for the number of physical units of S^i bought at the times t_n. In this framework, the usual self-financing condition reads: $\xi_{t_n}^1 - (\xi_{t_n}^2)^+ \pi_{t_n}^{12} + (\xi_{t_n}^2)^- / \pi_{t_n}^{21} \leq 0$ for each $n \leq N$. The associated portfolio starting with a zero initial holding is described as a 2-dimensional process $V_t^\xi := \sum_{t_n \leq t} \xi_{t_n}$ whose i-th component is the numbers of units of S^i held.

The key observation of [22] is the following: if $\tilde{Z}^2$ is a process such that $\tilde{Z}_t^2 \in [1/\pi_t^{21}, \pi_t^{12}]$ a.s. for all $t \leq T$, then the liquidation value at time T of the portfolio, $\ell(V_T^\xi) := V_T^{\xi,1} - (V_T^{\xi,2})^- \pi_T^{12} + (V_T^{\xi,2})^+ / \pi_T^{21}$, is a.s. lower than the terminal value $\tilde{V}_T^\xi := \sum_{t_n \leq T} \xi_{t_n}^2 (\tilde{Z}_{t_{n+1} \wedge T}^2 - \tilde{Z}_{t_n}^2)$ associated to the same strategy in a *fictitious market* in which the risky asset has the

dynamics $\tilde{Z}^2$ and where there is no transaction costs. In particular, if there is an equivalent measure $\mathbb{Q}$ such that $\tilde{Z}^2$ is a martingale, then no arbitrage is possible: $\ell(V_T^\xi) \in L^0(\mathbb{R}_+) \Rightarrow \tilde{V}_T^\xi \in L^0(\mathbb{R}_+) \Rightarrow \tilde{V}_T^\xi = 0 \Rightarrow \ell(V_T^\xi) = 0$. Thus the existence of such a process $\tilde{Z}^2$, called *fictitious price process*, admitting an equivalent martingale measure is a sufficient condition for the absence of arbitrage in this model.

The fundamental result of [22] is that this condition is actually also necessary, whenever we replace the notion of no-arbitrage by that of *no free lunch*.

As an example let us consider the case where $1/\pi^{21} = (1 - \lambda)S^2$ and $\pi^{12} = (1 + \lambda)S^2$ where S^2 is now viewed as a right-continuous adapted process and $\lambda \in (0, 1)$. Then, a necessary and sufficient condition for the absence of *free lunch* for simple strategies is that there exists a process $\tilde{Z}^2$ such that $\tilde{Z}_t^2 \in [(1 - \lambda)S_t^2, (1 + \lambda)S_t^2]$ a.s. for all $t \leq T$ and which is a martingale under some equivalent measure $\mathbb{Q}$. An important consequence of this result is that S^2 itself needs not admit a martingale measure nor be a semi-martingale under the original probability measure. One could for instance allow S^2 to be a fractional Brownian motion as in [16].

The multivariate case: the solvency region and its polar

In the multivariate setting where direct exchanges between many assets is possible, which is typically the case on currency markets, a similar reasoning can be used, and the geometric structure of the problem is more apparent. In particular, the notion of *solvency region*, introduced by Kabanov [29], and its positive polar play an important role.

The *solvency region* at time t is the set $K_t(\omega)$ formed by all vectors x such that we can find non-negative numbers a^{ij} satisfying $x^i + \sum_j(a^{ji} - a^{ij}\pi_t^{ij}(\omega)) \geq 0$. It corresponds to positions which can be transformed into non-negative holdings after suitable exchanges. A portfolio process, in units of physical quantities, is defined by [29] as a cadlag bounded variation process V satisfying $dV_t \in -K_t$. This means that there is a matrix-valued cadlag adapted process L, with non-decreasing components, such that $dV_t = \sum_j(dL_t^{ji} - dL_t^{ij}\pi_t^{ij})$, i.e. dL^{ij} is the number of units of asset j obtained by selling $dL_t^{ij}\pi_t^{ij}$ units of asset i.

In this model, a strategy is said to be admissible if the following *no-bankruptcy* condition holds: $V_t - a\mathbf{1} \in K_t$ a.s. for some real number a with $\mathbf{1} := (1, \ldots, 1)$. This means that the *liquidation value* of the portfolio is bounded from below by a.

The counterpart of the key observation of [22] is the following. Let Z be a continuous martingale with positive components such that Z_t takes values in the positive polar K_t^* of K_t: $K_t^*(\omega) := \{z \in \mathbb{R}^d : 0 \leq z^i \leq z^j\pi_t^{ji}(\omega)\}$. Then, by the intergration by parts formula, $Z_t \cdot V_t = \sum_i Z_t^i dV_t^i + V_t^i dZ_t^i$. The first part is non-positive because $Z_t \in K_t^*$ and $dV_t \in -K_t$, the second part is a local martingale, and $Z \cdot V$ is bounded from below by the martingale aZ. This implies that $Z \cdot V$ is a super-martingale, which rules out any arbitrage opportunities: $V_T \in L^0(K_T) \Rightarrow Z_T \cdot V_T \in L^0(\mathbb{R}_+) \Rightarrow Z_T \cdot V_T = 0 \Rightarrow V_T \in L^0(\partial K_T)$. Otherwise stated, if the liquidation value of the portfolio is non-negative a.s., then it must be equal to 0.

As in [22], the process Z has a nice interpretation in terms of *fictitious price process*. Indeed, if we set $\tilde{Z}^i = Z^i/(Z^1/\mathbb{E}[Z_T^1])$, we see that the above conditions imply that the *fictitious market*, without transaction costs and where the dynamics of the i-th asset is given $\tilde{Z}^i$, is *cheaper* than the original one ($\tilde{Z}^i/\tilde{Z}^j \in [1/\pi^{ij}, \pi^{ji}]$) and admits no arbitrage (there is at least one martingale measure $\mathbb{Q} := Z_T^1/\mathbb{E}[Z_T^1] \cdot \mathbb{P}$ for $\tilde{Z}$). See [6] for a precise statement.

Note that in this model no asset has been taken explicitly as a numéraire, except in the

last interpretation in terms of *fictitious markets*. It turns out that, when working with quantities instead of amounts, as in usual frictionless models, the only important quantity is the bid-ask spread process $\pi = (\pi^{ij})$ which directly expresses the exchange rates between two assets.

No-arbitrage conditions

Different notions of no-arbitrage have been proposed for discrete time multivariate models. In the following, we denote by A_T the set of terminal values of portfolios starting from 0.

1. The usual *no arbitrage* condition (NA) can be written as: $A_T \cap L^0(K_T) = L^0(\partial K_T)$, see above. It was studied by [32] and called *weak no arbitrage condition* therein . When the probability space is finite, it is equivalent to the existence of a martingale Z such that Z_t takes values in $K_t^* \setminus \{0\}$ for all $t \leq T$ a.s. We therefore retrieve the process Z required for the no-arbitrage condition of [29]. Moreover, this condition implies that A_T is closed in probability, a desirable feature to build on a nice duality for the set of super-hedgeable claims, see below. Such a process Z was called a *consistent price system* in [36]. The notion of consistency reflects the fact that the exchange rates corresponding to the induced frictionless market, see above, lie within the original bid-ask spreads: $\tilde{Z}^i/\tilde{Z}^j \in [1/\pi^{ij}, \pi^{ji}]$.

However, this condition is not strong enough when Ω is not finite, see [36]. This leads to the introduction of a second notion of no-arbitrage.

2. The *strict no arbitrage condition* (NA^s) introduced in [31] reads as follows: $A_t \cap L^0(K_t) = L^0(K_t^0)$ for all $t \leq T$. Here, $K_t^0 := K_t \cap (-K_t)$ $(= \partial K_t \cap (-\partial K_t))$. The economic interpretation is that, if a wealth process V starting from a zero initial endowment has a non-negative liquidation value at any time, then it is *equivalent* to 0, i.e. its liquidation value is 0 $(V_t \in \partial K_t)$ and it can be constructed from a 0 endowment at time t by a suitable immediate exchange on the market $(V_t \in -\partial K_t)$. Under the *efficient friction* condition: $1/\pi^{ij} < \pi^{ji}$ for all $i \neq j$, which means that no couple of assets can be exchanged freely and can be written as $K_t^0 = \{0\}$, this condition is equivalent to the existence of a martingale Z which lies in the relative interior riK_t^* of K_t^*, i.e. $Z^i/Z^j \in$ ri$[1/\pi^{ij}, \pi^{ji}]$. Moreover, it implies that A_T is closed in probability. Such a process Z is called a *strictly consistent price system*.

This last notion of no-arbitrage is sufficient to cover the cases where the transaction costs are strictly positive. However, up to the slight (also interesting) extension proposed [35], it does not allow to show that A_T is closed nor to construct a *consistent price system* in general without the extra *efficient friction* condition, see the counter-example in [36].

3. The last notion was proposed in Schachermayer [36]. It is based on the idea that if a martingale Z satisfies the condition $Z^i/Z^j \in$ ri$[1/\pi^{ij}, \pi^{ji}]$ then one can construct a bid-ask spread matrix $\bar{\pi}$ defined by $\bar{\pi}^{ji} := Z^i/Z^j$ which leads to a market without arbitrage, because Z is a martingale, and satisfies $[1/\bar{\pi}^{ij}, \bar{\pi}^{ji}] \subset$ ri$[1/\pi^{ij}, \pi^{ji}]$ by construction. Thus, the existence of a *strictly consistent price system* implies a strong notion of no arbitrage: there exists a market associated to a bid-ask spread matrix $\bar{\pi}$ satisfying $[1/\bar{\pi}^{ij}, \bar{\pi}^{ji}] \subset$ ri$[1/\pi^{ij}, \pi^{ji}]$ in which there is no arbitrage. Otherwise stated, one can slightly reduce the transaction costs, when they are not already equal to 0, and still preserve the (NA) condition. This condition was called the *robust no arbitrage* condition (NA^r) in [36]. The main result of this paper is that this condition is sufficient to ensure that A_T is closed in probability and is actually equivalent to the existence of a *strictly consistent price system*.

It seems that this is the good condition to impose on a model:

a- It is equivalent to the existence of a *strictly consistent price system* without any extra assumption.

b- When there is no friction, i.e. $1/\pi^{ij} = \pi^{ji}$ for all i, j, it is equivalent to the usual no-arbitrage condition in frictionless markets.

c- Similar notions can be used to study models with non-linear frictions, see [4].

d- It can be extended in continuous time models in the following form: the absence of arbitrage opportunities for arbitrary small transaction costs is equivalent to the existence of a *strictly consistent price system* for arbitrary small transaction costs. This result was proved in a model with only one risky asset with continuous paths by [19]. The existence of a *strictly consistent price system* for arbitrary small transaction costs in a multivariate market with continuous price processes is a result of [18].

2   Super-hedging and no-arbitrage price intervals

When there are transaction costs, we generally have, more than one fictitious price process and more than one martingale measure $\mathbb{Q}$ satisfying the conditions above. Furthermore, as underlined by [1], even if a contingent claim G can be duplicated by dynamic trading, the duplication strategy does not necessarily correspond to the cheapest way to hedge this claim. They thus introduced the concept of *super-replication price* $\pi(G)$ that corresponds to the minimum amount it costs to hedge the claim G (in terms of the first asset taken as a numéraire).

As first shown in [10] and [22], it can be obtained by taking the (normalized) expected value of $\tilde{Z}_T \cdot G$ with respect to all the *fictitious markets* $\tilde{Z}$ and all measures $\mathbb{Q}$ that characterize the absence of arbitrage opportunities in the corresponding *fictitious market*. Here, G is viewed as the vector of units of the different assets to be delivered. This result can easily be understood in the light of the above discussion. If $V_T - G \in K_T$, then $\tilde{Z}_T \cdot V_T \geq \tilde{Z}_T \cdot G$. Since $\tilde{Z} \cdot V$ is a $\mathbb{Q}$-super-martingale, see above, it follows that $\tilde{Z}_0 \cdot V_0 \geq \mathbb{E}^{\mathbb{Q}}[\tilde{Z}_T \cdot G]$. The converse implication is obtained by using a standard separation argument, once A_T is known to be closed in a suitable sense.

The no-arbitrage prices interval is then equal to $[-\pi(-G), \pi(G)]$. Using the viability concept for price systems introduced by [20], the paper [23] also prove that these bounds are the tightest bounds that can be inferred at the equilibrium on the price of a contingent claim without knowing the agent's preferences (see also [21]). This is still the case even if we assume that agents have VNM preferences (see [24]). In particular, this means that even if the super-replication price seems too high, see below, it is always possible to construct VNM agents that are willing to pay amounts arbitrarily close to this super-replication price in order to hedge the considered asset, see also [3].

Since endowments in different assets are not equivalent in the presence of transaction costs, it is also of interest to extend the notion of *super-hedging price* to that of *initial endowments* $x \in \mathbb{R}^d$ *that allow to super-hedge*. In this case, the above dual formulation reads $\tilde{Z}_0 \cdot x \geq \mathbb{E}^{\mathbb{Q}}[\tilde{Z}_T \cdot G]$ for all the *fictitious markets* $\tilde{Z}$ and all associated martingale measures $\mathbb{Q}$. See [32] and [7]. It can be restated in terms of consistent price systems: $Z_0 \cdot x \geq \mathbb{E}[Z_T \cdot G]$ for all *consistence price system Z*.

The case of American options can be treated similarly. However, it is not sufficient to impose the above condition at any stopping time lower than T as in frictionless markets.

This is due to the absence of total order on $\mathbb{R}^d$. To overcome this problem, one has to relax the notion of stopping times and consider the more general notion of *randomized* stopping times. See [5] and [9] for discrete time models, and [15] for a continuous-time extension.

The fact that this notion of *super-hedging* typically leads to much too high prices to serve in practice on the market (it usually corresponds to a buy-and-hold strategy) was first conjectured by [12] for call options and then proved by different authors at different level of generality, see [6] and the reference therein.

3   Utility maximization

Thanks to the above mentioned duality between super-hedgeable claims and consistence price systems, existence of optimal strategies can be obtained for general models with transaction costs. The first general result was derived by [10] in a Brownian diffusion model and then extended by [11] to the semi-martingale case. The general multivariate case was studied by [2] and [13] under *Asymptotic Elasticity* conditions similar to the one introduced in [33], see [17] for the necessity of this condition in models with proportional transaction costs. All these papers show that the usual duality holds once we replace the notion of *equivalent local martingale measures* by that of *consistent price systems*.

In Markovian diffusion models, the PDE approach has also attracted a lot of attention. It leads to HJB equations involving constraints on the gradients of the value function. It allows to show that the optimal strategy typically consists in maintaining the dotations in a given *no-trading region*. See e.g. [37], [30] and the references therein.

4   Generalizations and extensions

In order to take a large set of possible frictions into account including multivariate transaction costs, one can follow the approach of [8] (in discrete time), [26] and [28] (in continuous time) who propose to deal directly with the space of possible cash-flows, instead of the space of terminal payoffs, and provide a characterization of the No Free-Lunch assumption in terms of the existence of a separating functional. In particular, [34] develops an arbitrage pricing theory and a super-replication concept in this cash-flow space.

The case of fixed transaction costs is analyzed by [25] and [27]. They obtain that the absence of free-lunch is characterized by the existence of a (family of) martingale measure(s) for the frictionless price processes. The unique difference with the frictionless case consists in the fact that these martingale measures are not necessarily equivalent to the initial probability but only absolutely continuous with respect to it.
